Recap

A. Giovanidis 2020

In the previous course (Regression) we assumed that the real-world model is sufficiently described by a linear model with additive noise:

$$y = \beta_1 x + \beta_0 + \epsilon = f(x) + \epsilon$$

We estimated the unknown β 's by the parameters $\hat{\beta}_1, \hat{\beta}_0$.

The following formula predicts for any x

$$\hat{y} = \hat{\beta}_1 x + \hat{\beta}_0 = \hat{f}(x).$$

But we do not know anything about the noise!

Prediction Errors

These predictions cannot be accurate but will always have an irreducible error, no matter how good the choice of the predictor \hat{f} :

$$\mathbb{E}\left[(y-\hat{y})^2\right] = \mathbb{E}\left[(f(x)-\hat{f}(x))^2\right] + \mathbb{E}\left[\epsilon^2\right] + 2\mathbb{E}\left[\epsilon(f(x)-\hat{f}(x))\right].$$

$$= \mathbb{E}\left[(f(x)-\hat{f}(x))^2\right] + Var(\epsilon).$$

Two types of errors...

Reducible vs Irreducible

- ▶ The irreducible error, due to the random error ϵ in the model, whose variance is unknown.
- The reducible error, due to errors in the estimate of the model parameters $\hat{\beta}_i$. This type of error can be reduced by using (a) larger sample sets when estimating the coefficients, or (b) different models $\hat{f}(x)$ that better describe the unknown function f(x) (could be non-linear).

In practice larger intervals are used for prediction to account for both types of errors.

Accuracy

A. Giovanidis 2020

The MSE is a measure of model accuracy.

For the available data set $D_n = ((x_1, y_1), (x_2, y_2), \dots, (x_n, y_n)),$

$$MSE(D_n; \hat{\beta}_1, \hat{\beta}_0) = \frac{1}{n} \sum_{i=1}^n (y_i - \hat{\beta}_1 x_i - \hat{\beta}_0)^2.$$
 (1)

We guarantee maximum accuracy by

$$\min_{\hat{\beta}_1, \ \hat{\beta}_0} \ MSE(\frac{D_n; \hat{\beta}_1, \hat{\beta}_0}{\hat{\beta}_0}).$$

By choosing $\hat{\beta}_1$, $\hat{\beta}_0$ that minimize MSE we reduce the reducible part, but cannot change the irreducible part due to noise.

Train MSE

A. Giovanidis 2020

The predicted response $\hat{y}(x_i) = \hat{\beta}_1 x_i + \hat{\beta}_0$ will be close to y_i , because the parameters are chosen to minimise their difference! We say that the model is trained with data D_n .

$$MSE_{train} = MSE(D_n; \hat{\beta}_1, \hat{\beta}_0).$$

But! We actually want that the model predicts good values for unknown data, $x_o \notin D_n$.

$$\hat{y}_o = \hat{\beta}_1 x_o + \hat{\beta}_0.$$

Test MSE

A. Giovanidis 2020

We need a different test data set D_m^{test} with a number $m \ge 1$ of samples, to test the accuracy of our prediction model. For this test data set, we relate the accuracy metric

$$MSE_{test} := MSE(D_m^{test}; \hat{\beta}_1, \hat{\beta}_0) \neq MSE_{train}.$$

Question 1: How good does our "minimum MSE linear predictor" behave for the test data set?

Question 2: If we use other prediction models $\hat{f}(x)$, e.g. non-linear, can these predict better for the same test data set?

Polynomial Regression

A. Giovanidis 2020

The linear regression model assumes a linear relationship between the response and the input (predictors).

But! the true relationship may be non-linear.

Extend the linear model, using polynomial regression.

For 1-D input x we write an ℓ -polynomial model:

$$y = \beta_0 + \beta_1 x + \beta_2 x^2 + \ldots + \beta_\ell x^\ell + \epsilon = f(x) + \epsilon.$$
 (2)

But it is still a linear model for the parameters!

If we regard $x_1 := x$, $x_2 := x^2$,..., $x_\ell := x^\ell$ it is just a multiple linear regression.

 \rightarrow Use standard linear regression software.

Polynomial Fit

A. Giovanidis 2020

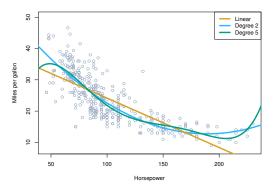

Figure: Polynomial vs Linear fit.¹

¹Source [B.1]

Flexibility VS Interpretability

A. Giovanidis 2020

Higher order polynomial models offer more flexibility. (see Question 2)

In the most extreme case we can use a model whose curve passes through every point of the train data set D_n . We can propose a polynomial fit with $\ell = card(D_n)$. Is this a good predictive model?

At the other extreme we can use a very restrictive model (simple linear regression), with $\ell=1$.

Maybe this simple model is better?

A. Giovanidis 2020

Model Fitting I

Optimal mode selection

A. Giovanidis 2020

Answer to Question 1:

The MSE_{test} is always higher than noise (irreducible error).

Answer to Question 2:

The more flexibility (higher poly-degree ℓ), the lower the MSE_{train} .

But! The MSE_{test} always has a $\ensuremath{\mathbf{U}}$ shape (fundamental property) with respect to degree (x-axis). The optimal mode is the one that minimizes the MSE_{test} : trade-off between flexibility vs interpretability.

We call this the Variance VS Bias trade-off.

Overfitting / Underfitting

A. Giovanidis 2020

Overfitting: Small MSE_{train} but large MSE_{test} . The statistical learning model picks patterns that are caused by randomness rather than the true properties of the unknown f(x).

needs lower flexibility!

Underfitting: Large MSE_{train} and large MSE_{test} . The learning model is too rigid to accurately describe the unknown f(x).

reds higher flexibility!

A. Giovanidis 2020

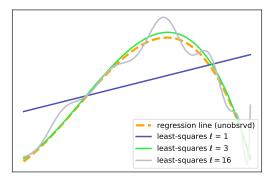

Figure: Polynomial Over/Under- fitting.

MSE(Train) = (46.41, 25.66, 24.67), min train MSE for $\ell = 16$. MSE(Test) = (59.30, 42.94, 45.70), min test MSE for $\ell = 3$.

Numerical Example - Polynomial fit

A. Giovanidis 2020

Consider the numerical example with $D_n = \{(1,3), (2,4), (3,8), (4,14)\}.$

- ▶ With the first three set elements do linear regression.
- Use the forth element to derive the $MSE_{test-linear}$.
- ▶ With the first three set elements do quadratic regression.
- ▶ Use the forth element to derive the $MSE_{test-quadratic}$.

Which method is best?

Numerical Example - Polynomial fit cont'd^{A. Giovanidis 2020}

We use the set $D_3 = \{(1,3), (2,4), (3,8)\}$ for the linear regression, and we get:

 $\hat{y} = 2.50x + 0$, with an $MSE_{test-linear} = 16$.

for the quadratic regression $\beta = (\mathbf{X}\mathbf{X}^T)^{-1}\mathbf{X}^T\mathbf{y}$, and we get:

$$\hat{y} = 1.50x^2 - 3.5x + 5$$
, with an $MSE_{test-quadratic} = 1$.

 $MSE_{test-quadratic} < MSE_{test-linear}$ \bowtie the quadratic fit is better!

Resampling

A. Giovanidis 2020

In all the above, we assumed that two disjoint data-sets are available:

- ightharpoonup a train data-set D_n ,
- ► a test data-set D_m^{test} ,

where $D_n \cap D_m^{test} = \emptyset$.

However, usually we only have one data-set available D_n , to both train and test the machine learning algorithm.

What should we do? a. Cross-validation, or b. Bootstrapping!

Validation set approach

A. Giovanidis 2020

Naive approach. Split the observation data set D_n in two:

- a train set
- ▶ a validation set

e.g. 80% of the elements of D_n belong to the train and the rest 20% to the test set.

- ▶ Use the train set to fit the model.
- ▶ Use the validation set to evaluate performance, e.g. MSE_{test} .

Validation set Example

A. Giovanidis 2020

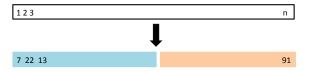

Figure: n observations randomly split into a Train and Validation set.⁵

⁵Source [B.1]

Drawbacks

A. Giovanidis 2020

The method has two main problems:

- 1. The test error rate depends on the data split
 - $\rightarrow MSE_{test}$ can be highly variable!
- 2. Not all available n data are used for training
 - \rightarrow worse performance with less observations, and MSE_{test} is
 - overestimated!

A. Giovanidis 2020

Validation set Example

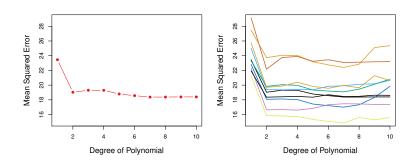

Figure: Variability of the MSE_{test} depending on the data split.⁶

⁶Source [B.1]

LOOCV

A. Giovanidis 2020

Leave-one-out-Cross-Validation. Split the data set D_n again in two:

- ▶ a validation set of a single observation (x_1, y_1)
- ▶ a train set of the rest n-1 observations .

A prediction \hat{y}_1 is made only for the excluded observation using x_1 .

$$MSE_{test} = MSE_1 = (y_1 - \hat{y}_1)^2.$$

► Problem: The evaluation is based on a single observation → highly variable.

LOOCV x n

A. Giovanidis 2020

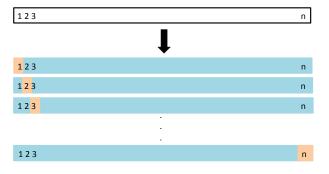

Figure: Solution: repeat n times, for n different splits !⁷

⁷Source [B.1]

LOOCV x n

A. Giovanidis 2020

The LOOCV estimate for the test MSE is the average of these n test error-estimates

$$CV_{(n)} = \frac{1}{n} \sum_{i=1}^{n} MSE_i.$$

No randomness in the result + uses all observations!

k-fold CV

A. Giovanidis 2020

For large n LOOCV is time-consuming to calculate all MSE_i .

■Better use k-fold Cross-Validation:

- ▶ The data-set D_n is split into $1 \le k \le n$ folds.
- ▶ The 1st fold is treated as validation set and the rest k-1 for training $\rightarrow MSE_1$ is caclulated.
- ▶ Repeat k times by choosing a different fold for validation set each time $\rightarrow MSE_k$ is calculated.

The k-fold estimate is computed by averaging

$$CV_{(k)} = \frac{1}{k} \sum_{i=1}^{k} MSE_i.$$

k-fold x k

A. Giovanidis 2020

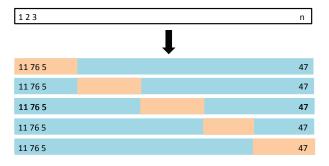

Figure: Repeat k times, for k different splits !8

⁸Source [B.1]

k-fold CV

A. Giovanidis 2020

Computational advantages over LOOCV:

- ▶ LOOCV is a special case of k-fold CV, for k = n.
- ▶ In practice k = 5 or k = 10.
- ▶ k-fold CV with k < n can have lower variance in the MSE, than LOOCV.

LOOCV vs k-fold CV

A. Giovanidis 2020

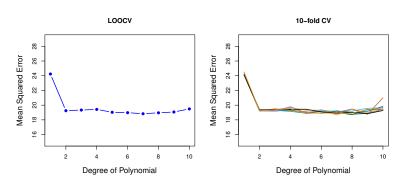

Figure: Mode selection with two CV methods⁹.

The 10-fold was run 10 times, each with a different data split.

⁹Source [B.1]

The Bootstrap

A. Giovanidis 2020

A powerful tool that can quantify the uncertainty associated with a given learning method.

e.g. it can estimate the standard error (SE) of $\hat{\beta}_k$, or MSE_{test} ,...

Main idea:

Given an original data-set $Z = D_n$, create B > 1 new datasets of size n:

each new dataset Z^{*b} results from uniform sampling with replacement of the set Z.

 \square for each Z^{*b} calculate the unknown $\hat{\alpha}^{*b}$.

Resampled Data Sets

A. Giovanidis 2020

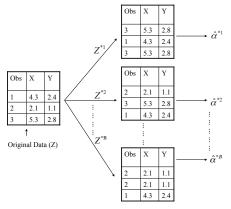

Figure: Example of Z^{*b} sets, $b = 1, 2, ..., B.^{10}$.

¹⁰ Source [B.1]

Bootstrap estimates

A. Giovanidis 2020

▶ The Average

$$Av_B(\hat{\alpha}) = \bar{\alpha} = \frac{1}{B} \sum_{b=1}^B \hat{\alpha}^{*b}$$

The Standard Error

$$SE_B(\hat{\alpha}) = \sqrt{\frac{1}{(B-1)}\sum_{b=1}^B (\hat{\alpha}^{*b} - \overline{\alpha})}$$

Numerical Example - Resampling

A. Giovanidis 2020

Consider the numerical example with $D_n = \{(1,3), (2,4), (3,8), (4,9)\}.$

Use this set and apply:

- ► Simple Validation.
- ► LOOCV.
- ► 2-fold CV.
- Bootstrapping.

Numerical Example - Simple Validation

A. Giovanidis 2020

Suppose first that we split the D_n in half, into a

- ► Train Set {(1,3), (2,4)}.
- ► Validation Set {(3,8),(4,9)} .

Then $\hat{y} = 1 \cdot \hat{x} + 2$.

- \blacktriangleright $MSE_{train} = 0$.
- $MSE_{test} = \frac{(5-8)^2 + (6-9)^2}{2} = 9$.

Numerical Example - LOOCV

A. Giovanidis 2020

```
We apply 4 times LOOCV
                  Train
                                 Validate
 Fold 1 \mid \{(2,4), (3,8), (4,9)\} \mid (1,3)
 Fold 2 \{(1,3), (3,8), (4,9)\}\ (2,4)
 Fold 3 \{(1,3), (2,4), (4,9)\} \{(3,8)\}
 Fold 4 \{(1,3), (2,4), (3,8)\} \{(4,9)\}
```

We get

$$Av(MSE_{test}) = \frac{1+1.638+1.664+1}{4} = 1.3255$$

Numerical Example - 2Folds

A. Giovanidis 2020

```
We apply 2-Folds (with shuffle)
 Fold 1 \{(3,8), (2,4)\} \{(1,3), (4,9)\}
 Fold 2 \{(1,3), (4,9)\} \{(3,8), (2,4)\}
We get
 Fold 1 | \hat{y} = 4.00x - 4.00 | MSE_{test,1} = 9
 Fold 2 \hat{y} = 2.00x + 1.00 MSE_{test,2} = 1
Av(MSE_{test}) = \frac{9+1}{2} = 5.
```

Numerical Example - Bootstrapping

A. Giovanidis 2020

Consider the numerical example with $D_n = Z_1 = \{(1,3), (2,4), (3,8), (4,9) \}.$

Apply the bootstrapping technique for 3 more sample sets :

- $Z_2^* = \{(2,4), (2,4), (4,9), (4,9) \}.$
- $Z_3^* = \{(2,4), (1,3), (3,8), (4,9) \}.$
- $Z_4^* = \{(2,4), (4,9), (3,8), (3,8) \}.$

Numerical Example - Bootstrapping cont' \hat{d} I $^{\text{Giovanidis }2020}$

We get for each of the four sets,

- 1. $(\hat{\beta}_0, \ \hat{\beta}_1) = (0.5, \ 2.2)$.
- 2. $(\hat{\beta}_0, \ \hat{\beta}_1) = (-1.0, \ 2.5)$.
- 3. $(\hat{\beta}_0, \ \hat{\beta}_1) = (0.5, \ 2.2)$.
- 4. $(\hat{\beta}_0, \ \hat{\beta}_1) = (-0.25, \ 2.5)$.

$Numerical\ Example\ -\ Bootstrapping\ cont'd\ IG^{Giovanidis}\ 2020$

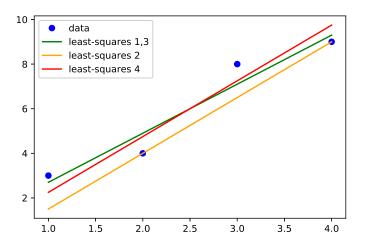

Figure: Bootstrap Regression Lines.

Numerical Example - Bootstrapping cont'd III

We have obtained the following set of estimates for the intercept and the slope

- $\hat{\beta}_0 = [0.5, -1.0, 0.5, -0.25]$.
- $\hat{\beta}_1 = [2.2, 2.5, 2.2, 2.5]$.

Then

- $\bar{\beta}_0 = Av_4(\hat{\beta}_0) = -0.0625$ and $SE_4(\hat{\beta}_0) = 0.3590$.
- $\bar{\beta}_1 = Av_4(\hat{\beta}_1) = 2.35 \text{ and } SE_4(\hat{\beta}_1) = 0.0867.$

95% confidence intervals:

- $\beta_0 \in [-0.7806, +0.6556].$
- $\beta_1 \in [+2.1768, +2.5232].$

A. Giovanidis 2020
